The transient response of an elastic cylinder to a laser impact is studied. When the laser source is a line perpendicular to the cylinder axis, modes guided along the cylinder are generated. For a millimetric steel cylinder up to ten narrow resonances can be locally detected by a laser interferometer below 8 MHz. These resonances correspond to Zero-Group Velocity guided modes or to circumferential modes. We observe that the theory describing the propagation of elastic waves in an isotropic cylinder is not sufficient to precisely predict the resonance spectrum. In fact, the texture of such elongated structure manifests as elastic anisotropy. Thus, a transverse isotropic (TI) model is used to calculate the dispersion curves and compare them with the measured ones, obtained by moving the source along the cylinder. The five elastic constants of a TI cylinder are adjusted leading to a good agreement between measured and theoretical dispersion curves. Then, all the resonance frequencies are satisfactorily identified.

I. INTRODUCTION

Elongated cylindrical structures like rods, cable strands, or fibers are widely used in the industry or in civil engineering. Characterization of mechanical properties of constitutive materials is important for testing their structural integrity. Non-Destructive Evaluation (NDE) of these properties is usually carried out with elastic waves. Various methods like Resonant Ultrasonic Spectroscopy (RUS)/pulse-echo contact-method, or pulsed/continuous laser-ultrasound (LU) contactless-method are used. Cylindrical structures support the propagation along their axes of elastic waves of different types: longitudinal (L), flexural (F), or torsional (T). Many theoretical and numerical studies and few experimental results were published the past 50 years on the propagation of time harmonic guided modes in solid or hollow cylinders.46–48 In the 19th century, Pochohammer49 and Chree50 first established the equation of longitudinal waves in free isotropic cylindrical structures. In 1943, Hudson studied the fundamental flexural mode in a solid cylinder51 and longitudinal modes of a bar were examined by Davies52 in 1948. Gazis reported the first exact solutions of the frequency equation,46 as well as a complete description of propagative modes, displacement, and stress distributions for an isotropic elastic hollow cylinder in vacuum. Pao and Mindlin53,54 as well as Onoe et al.55 studied all the branches of the complete three-dimensional problem of a free solid cylinder. A thorough review of elastic wave propagation in isotropic elastic cylinders and plates was given by Meeker and Meitzler.48 Later, Zemanek investigated elastic wave propagation in a cylinder, both experimentally and theoretically.56

All these works deal with isotropic material, however transverse anisotropy is exhibited by elongated cylindrical structures due to their manufacturing processes (poly-crystalline metals)57 or their texture (carbon fibers used in reinforced polymers). Then, non-destructive measurement of elastic constants of transverse isotropic (TI) materials is of great interest,58 especially in aeronautic and aerospace industries. Morse first established the frequency equation for longitudinal waves propagating in TI cylinders.59 The extension of Gazis formulation to orthotropic and TI waveguides was initiated by Mirsky in 1964 for infinite and finite cylinders.60,61 Then, several researchers investigated the propagation or the scattering of elastic waves in free or fluid-loaded TI cylinders.62–66 Ahmad and Rahman67 also studied the scattering of acoustic wave incident on a TI cylinder and showed that Buchwald’s representation68 yields much simpler equations.69 This representation is beneficial to simplify the description of the potential functions and economizes laborious calculations. This model provides perfectly similar results with Honarvar and Sinclair model70,71 and can be applied to study both isotropic and TI cylinders. Honarvar et al. also obtained the frequency equations of axisymmetric and asymmetric free vibrations of finite TI cylinders.72 Several other researchers proposed to use the impedance matrix theory73,74 or a semi-analytical finite element method to study transient thermoelastic waves in isotropic/anisotropic cylinders.75

Frequency equations determining the angular frequency ω(= 2πf) versus the axial wave number k(= 2π/λ) have to be solved numerically. For a given circumferential order n, the various solutions (integer m) can be grouped into different families: longitudinal L(0, m) and torsional T(0, m) modes with displacements independent of the azimuthal angle θ, or flexural F(n, m) modes with displacements varying as sin nθ or cos nθ. Each mode is represented by a dispersion curve ω(k). Many similarities exist between the families of modes found in plates and cylinders. Indeed, torsional modes T(0, m) are similar to shear horizontal modes SH in plates. Longitudinal L(0, m) and first flexural F(1, m) modes in cylinders are analogous to symmetrical S_m and anti-symmetrical A_m Lamb modes in plates. Major differences appear in the frequency spectrum for flexural modes F(n, m) with family number n ⩾ 2.
The laser-based ultrasonic technique is a convenient tool for the generation and detection of guided elastic waves in plates or cylinders. It has been shown that this non-contact technique is very efficient to observe Zero Group Velocity (ZGV) Lamb modes corresponding to a frequency minimum of the dispersion curves $\omega(k)$. At the ZGV frequencies, guided modes have a finite phase velocity but vanishing group velocity. The interference of forward and backward guided waves having opposite wave numbers gives rise to a standing wave pattern. For these specific points, the energy deposited by the laser pulse remains trapped under the source. The resulting local and narrow resonances can be detected at the epicenter with an optical interferometer. This non-contact method allowed us to perform accurate measurements of elastic properties of isotropic or TI materials. For cylinders, a line laser source can be used to control the propagation direction. For a line source parallel to the cylinder axis, circumferential Rayleigh and whispering gallery waves are excited giving rise to resonances at all $n$ integer values of the normalized circumferential wave number $ka$. This configuration was also used by Mounier et al. to study resonances of a micrometric fiber at sub-gigahertz frequencies and to determine the elastic constants using an isotropic model. Circumferential resonances occur at cut-off frequencies of longitudinal and flexural modes where the axial wave number vanishes. They are analogous to thickness resonances in plates at cut-off frequencies of Lamb modes. In the case of a TI cylinder, this configuration is not appropriate to determine the whole set of elastic constants.

In this paper, we investigate the mechanical response of a transversely isotropic cylinder to a laser line source perpendicular to the axis. In this case, the generated waves guided along the cylinder axis are sensitive to the material anisotropy. We performed measurements in a millimeter steel cylinder and many resonances are observed in the megahertz range. They can be roughly identified from the minimum frequency of some branches of the dispersion curves of longitudinal and flexural modes calculated for an isotropic cylinder. However, significant discrepancies remain between the isotropic model and experimental resonance frequencies. Dispersion curves are then calculated using a TI model. The five independent elastic constants are adjusted such that all measured resonance frequencies can be precisely predicted. Moreover, experimental dispersion curves, measured by moving the laser source, are compared with the theoretical ones.

II. EXPERIMENTS

Measurements were performed with an optical interferometer at the center of the source. Compared to a point source, the use of a laser line perpendicular to the cylinder axis significantly reduces the excitation of most circumferential modes. Resonances were extracted from the spectrum of the temporal signal. Their frequencies were compared with minimum frequencies of dispersion curves calculated from an isotropic material.

A. Laser-ultrasonic setup

The experimental setup is shown Fig. 1. The sample is an austenitic stainless steel (AISI 304L) solid cylinder (length 420 mm, diameter $2a = 0.775$ mm, and mass density is $\rho = 7.91 \times 10^3$ kg·m$^{-3}$). The rod is supported by two beveled metallic pieces to reduce the mechanical contact (friction). Elastic waves were generated by a Q-switched Nd:YAG (yttrium aluminium garnet) laser providing 8-ns pulses of 15-mJ energy at a 100-Hz repetition rate (Quantel Centurion). The spot diameter of the unfocused beam is equal to 2.5 mm. A beam expander ($\times 4$) and a cylindrical lens (focal length 250 mm) were used to enlarge and focus the laser beam into a narrow line on the surface. The optical energy distribution was close to a Gaussian and the absorbed power density was below the ablation threshold. The full length of the source at $1/e$ of the maximum value was found to be 10 mm and the width was estimated to be 0.3 mm. In the thermoelastic regime, the line source is equivalent to a set of force dipoles distributed on the surface and parallel to the cylinder axis. The estimated Rayleigh range of the Gaussian laser beam (0.8 mm) is only twice the cylinder radius (0.39 mm). Then, the energy deposited along the cylinder circumference depends on the azimuthal angle $\theta$. Moreover, the optical absorption decreases with $\theta$ from the normal incidence ($\theta = 0$) on both sides of the sample. A priori, this asymmetry favors the excitation of some flexural modes.

![Figure 1](color online) Source and probe geometry used to excite and to detect local resonances in a cylinder. S: laser source, I: interferometer, C: cylindrical lens.

Local vibrations were measured by a heterodyne interferometer equipped with a 100-nW frequency doubled...
Nd:YAG laser (optical wavelength $\Lambda= 532$ nm). This interferometer is sensitive to any phase shift $\Delta \phi$ along the path of the optical probe beam, and then to the mechanical displacement $u_\phi$ normal to the surface. The calibration factor (85 nm/V), deduced from the phase modulation $\Delta \phi = 2\pi u_\phi / \Lambda$ of the reflected beam, was constant over the detection bandwidth (20 kHz - 20 MHz). Large low frequency phase-shifts due to thermal effects or first flexural $F(1,1)$ mode are eliminated by amplification, before amplification, a high-pass filter having a cut-off frequency equal to 1.5 MHz. Measurements were conducted at room temperature (21 ± 0.5°C). Signals detected by the optical probe were fed into a digital sampling oscilloscope and transferred to a computer.

### B. Zero-group velocity resonances

The propagation of elastic waves along the cylinder axis is represented by dispersion curves calculated from Zemanek’s equation.\textsuperscript{56} The steel sample is assumed to be homogeneous with longitudinal and transverse velocities $V_L = 5650$ m/s and $V_T = 3010$ m/s, respectively. The numerical algorithm used to find the roots of the secular equation was proposed by Seco and Jiménez.\textsuperscript{87} Firstly, the cut-off frequencies are evaluated with a bisection method, then a zero-finding algorithm is applied to determine each branch successively. The roots were obtained with an acceptable error of less than $10^{-6}$. Finally, the dispersion curves are determined for longitudinal modes and the first seven families of flexural modes in less than 1 minute on a personal computer, with a resolution $\Delta k = 10^{-3}$ mm$^{-1}$. As shown in Fig. 2(a), dispersion curves obtained for longitudinal $L(0, m)$ and first flexural $F(1, m)$ modes are similar to those obtained for an isotropic elastic plate. Dispersion curves of higher order flexural modes $F(n, m)$ are plotted in Fig. 2(b). As the interferometer is only sensitive to the normal displacement, torsional modes are not presented. Branches of the dispersion curves are obtained separately, thus ZGV frequencies are easily determined by searching for minimum frequencies for finite wave numbers.

A typical signal, corresponding to the mechanical displacement normal to the cylinder surface, is given in Fig. 3(a). As previously explained, the oscillations in the first 5 $\mu$s are due to the large displacements associated with the low frequency components of the flexural mode $F(1,1)$ similar to the $A_0$ mode in plates. As shown in the insert, the low amplitude tail for $t > 5$ $\mu$s is not noise but high frequency oscillations due to ZGV or circumferential resonances. The spectra of out-of-plane displacement are shown in Fig. 3(b). Seven resonances dominate between 1.5 and 8 MHz. The peak at 2.77 MHz can be ascribed to the ZGV resonance at the minimum frequency of the $F(2,1)$-mode, while peaks at 4.38 and 4.29 MHz correspond to $L(0, 2)$ and $F(3, 1)$-ZGV modes, respectively. The peak at 3.42 MHz can be associated with a circumferential resonance (horizontal arrow in Fig. 2(a)) at the cut-off frequency (3.46 MHz) of the $F(1, 3)$ mode. The peak at 5.61 MHz is relatively close to the minimum frequency (5.79 MHz) of the $F(4, 1)$ mode. Higher frequency peaks at 6.83 and 7.70 MHz do not correspond to any minimum frequency on the dispersion curves. Except for $L(0, 2)$ which is estimated at 0.2%, relative errors from 2% to 4% are observed for the other resonances. The good agreement for the $L(0, 2)$ and $F(1, 3)$ resonances was obtained with the chosen pair of bulk wave velocities. Another pair of velocities ($V_L = 5500$ m/s, $V_T = 2920$ m/s) is needed to accurately predict the resonance frequencies of higher order modes ($n > 2$). Thus, the isotropic model with two elastic constants is not suitable. A higher number of material parameters are required for a better prediction of the resonance frequencies. In the following section, we apply the model with five elastic constants, developed by Ahmad and Rahman for TI cylinder.\textsuperscript{67}

The Q-factor ($Q = f_0 / \Delta f_0$) can be estimated from the half-power width $\Delta f_0$ of the resonance peak at the ZGV point. In order not to underestimate the Q-factor, the signal acquisition time window $\Theta$ must be larger than the inverse of the bandwidth. We performed a measurement of the out-of-plane displacement at the epicenter with a signal acquisition time window $\Theta = 4$ ms. We obtained thinnest resonances and a Q-factor at $L(0, 2)$-ZGV frequency of $4 \times 10^3$ ($\Delta f = 1.1$ kHz and $f_0 = 4.38$ MHz). For flexural ZGV resonances, the Q-factor are slightly

\begin{figure}[h]

\end{figure}
lower and vary from $2 \times 10^3$ to $2.5 \times 10^3$. With such high Q values, the influence of the ultrasound attenuation can be neglected.

III. TRANSVERSE ISOTROPIC MODEL

In the linear theory of elasticity, anisotropic media are described by the stiffness tensor $c_{ijkl}$ (with $i$, $j$, $k$, $l = 1$ to 3). Using the Voigt’s notation, they are represented by a $6 \times 6$ symmetric matrix $c_{\alpha\beta}$ ($\alpha, \beta = 1$ to 6). Given the Cartesian coordinates $(x_1, x_2, x_3)$ with the $x_3$-axis parallel to the cylinder $z$-axis, the sample is supposed to be isotropic in the $(x_1, x_2)$ plane. Such transverse isotropic medium is described by five independent elastic constants: $c_{11}$, $c_{13}$, $c_{33}$, $c_{44}$, and $c_{66}$. Other elastic constants are related to these coefficients: $c_{22} = c_{11}$, $c_{23} = c_{13}$, $c_{55} = c_{44}$, $c_{12} = c_{11} - 2c_{66}$ or vanish.

A. Dispersion equation

As mentioned by Honarvar et al.,\textsuperscript{71} the displacement vector $u(r, \theta, z, t)$ can be derived from three scalar potential functions $\varphi$, $\chi$, and $\psi$.\textsuperscript{70,88} A simple representation initiated by Buchwald\textsuperscript{98} and used by Ahmad and Rahman\textsuperscript{87} is the following:

$$u = \nabla \varphi + \nabla \times (\chi \hat{e}_z) + \left(\frac{\partial \psi}{\partial z} - \frac{\partial \varphi}{\partial z}\right) \hat{e}_z. \quad (1)$$

In cylindrical coordinates $(r, \theta, z)$, the above representation leads to the following displacement components:

$$(u_r, u_\theta, u_z) = \left(\frac{\partial \varphi}{\partial r} + \frac{1}{r} \frac{\partial \chi}{\partial \theta}, \frac{\partial \varphi}{\partial \theta} + \frac{\partial \chi}{\partial r}, \frac{\partial \psi}{\partial z}\right).$$

Harmonic solutions are given by

$$\varphi_n = \Phi J_n(\beta r) \cos(n \theta) \exp[i(kz - \omega t)],$$
$$\psi_n = \Psi J_n(\beta r) \cos(n \theta) \exp[i(kz - \omega t)],$$
$$\chi_n = X J_n(\beta r) \sin(n \theta) \exp[i(kz - \omega t)],$$

where $J_n$ is the Bessel function of the first kind of order $n$. They correspond to the superposition of plane waves of wave vector $k = (\beta \cos \theta, \beta \sin \theta, k)$ which satisfy the propagation equation in a meridian plane. The radial component $\beta$ of the wave vector $k$ must satisfy the Christoffel equation

$$\left(c_{11}c_{44}\beta^4 - E\beta^2 + F\right) \left(c_{66}\beta^2 + c_{44}k^2 - \rho \omega^2\right) = 0. \quad (2)$$

The first term corresponds to waves polarized in the meridian plane ($x_2, x_3$) and the second term corresponds to pure shear wave (polarized along $x_1$). The coefficients $E$ and $F$ are given in the appendix [Eq. (A.2)].

The above equations are similar to those obtained by Mirsky.\textsuperscript{91} Omitting the propagation term $\exp i(kz - \omega t)$ for simplicity, the three independent solutions are found to be

$$(\varphi_{1n}, \psi_{1n}, \chi_{1n}) = \left(J_n(\beta_1 r) \cos(n \theta), q_1 J_n(\beta_1 r) \cos(n \theta), 0\right),$$
$$(\varphi_{2n}, \psi_{2n}, \chi_{2n}) = \left(q_2 J_n(\beta_2 r) \cos(n \theta), J_n(\beta_2 r) \cos(n \theta), 0\right),$$
$$(\varphi_{3n}, \psi_{3n}, \chi_{3n}) = \left(0, 0, J_n(\beta_3 r) \sin(n \theta)\right).$$

The three roots of the Christoffel equation, $\beta_1$, $\beta_2$, and $\beta_3$ are given in Eq. (A.3) and $q_1$, $q_2$ are the potential amplitude ratios provided by Eq. (A.4). Hence, the displacements are as follows:

$$\begin{align*}
(u_{1r}, u_{1\theta}, u_{1z}) &= \left(\beta_1 J'_n(\beta_1 r) \cos(n \theta), -\left(\frac{n}{r}\right) J_n(\beta_1 r) \sin(n \theta), ikq_1 J_n(\beta_1 r) \cos(n \theta)\right), \\
(u_{2r}, u_{2\theta}, u_{2z}) &= \left(q_2 \beta_2 J'_n(\beta_2 r) \cos(n \theta), -\left(\frac{n}{r}\right) q_2 J_n(\beta_2 r) \sin(n \theta), ik J_n(\beta_2 r) \cos(n \theta)\right), \\
(u_{3r}, u_{3\theta}, u_{3z}) &= \left(\frac{n}{r}\right) J_n(\beta_3 r) \cos(n \theta), -\beta_3 J'_n(\beta_3 r) \sin(n \theta), 0\right).
\end{align*}$$

Laurent et al: Resonances in transversely isotropic cylinder
The spatial Fourier transform was extended to the meridian plane. The last solution having zero displacement component along the z-axis corresponds to a pure shear wave. These solutions must be combined with weighting factors $B_n, C_n, D_n$ to satisfy the boundary conditions at the free surface $r = a$. These conditions imply that normal stresses vanish: $\sigma_{rr}(a) = \sigma_{r\theta}(a) = \sigma_{rz}(a) = 0$ and lead to the following homogeneous linear system:

$$\begin{bmatrix}
a_{11} & a_{12} & a_{13} \\
a_{21} & a_{22} & a_{23} \\
a_{31} & a_{32} & a_{33}
\end{bmatrix} \begin{bmatrix} B_n \\ C_n \\ D_n \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}, \quad (4)$$

where the matrix elements $a_{ij}$ are listed in Eq. (A.1). The dispersion equation results from the secular equation

$$\det(a_{ij}) = 0. \quad (5)$$

For $n = 0$, Eq. (5) splits into two parts: $a_{23} = 0$, i.e., $(\beta_3 a) J'_n(\beta_3 a) = J'_n(\beta_3 a)$ similar to the equation given by Mirkzy for torsional modes $T(0, m)$ and $a_{11}a_{32} = a_{12}a_{31}$ corresponding to longitudinal modes $L(0, m)$.

### B. Cutoff frequencies

As the wave number $k$ is equal to zero, the motion at the cutoff frequencies is independent of the axial coordinate $x_3$. This implies $k^2 q_1 = 0$, $q_2 = 0$, and $a_{12} = a_{22} = 0$. The dispersion equation [Eq. (5)] for longitudinal and flexural modes in a solid cylinder at $k = 0$ reduces to

$$\beta_2 a J'_n(\beta_2 a)(a_{13}a_{21} - a_{11}a_{23}) = 0, \quad (6)$$

where the four $a_{ij}$ simplify as

$$a_{11} = c_{11}(\beta_1 a)^2 J''_n(\beta_1 a) + c_{12}\{(\beta_1 a) J'_n(\beta_1 a) - n^2 J_n(\beta_1 a)\},$$

$$a_{13} = 2nc_{66}\{(\beta_3 a) J'_n(\beta_3 a) - J_n(\beta_3 a)\},$$

$$a_{21} = -2n\{(\beta_1 a) J'_n(\beta_1 a) - J_n(\beta_1 a)\},$$

$$a_{23} = -(\beta_3 a)^2 J''_n(\beta_3 a) + (\beta_3 a) J'_n(\beta_3 a) - n^2 J_n(\beta_3 a).$$

To find the cutoff frequencies, the above equation can be solved for $\omega_n(= 2\pi f_n)$, for various values of $n$ and $m$. The first two roots $\beta_{1,2}$ are simplified using the reduced expressions of $\Delta = (c_{11} - c_{44})\omega_c^2$, $E = (c_{11} + c_{44})\rho\omega_c^2$, and $F = \rho^2\omega_c^4$ [Eq. (A.3)] as $\beta_1 = \omega_c\sqrt{\rho/c_{11}}$ and $\beta_2 = \omega_c\sqrt{\rho/c_{44}}$. The third root reduces to $\beta_3 = \omega_c\sqrt{\rho/c_{66}}$. The cutoff frequency equation [Eq. (6)] is simplified as $a_{11} J'_n(\beta_2 a) = 0$ for $L(0, m)$.

### C. Dependence of ZGV frequencies on elastic constants

A sensitivity analysis was performed to characterize the elastic constant influence on the dispersion curves and especially on ZGV frequencies. Figure 4 displayed the longitudinal and the first two flexural mode families as a function of elastic constants. Each constant was successively varied by $\pm 5\%$ and $\pm 10\%$ around the following average values (in GPa): $c_{11} = 240, c_{13} = 110, c_{33} = 250, c_{44} = 70$, and $c_{66} = 70$. The curves obtained for the average values are displayed by the dashed line. It appears that each ZGV resonance depends on specific constants. For example, the elastic constants which mainly affect the L(0,2)-ZGV frequency are $c_{11}$ and $c_{44}$. These elastic constants are proportional to the square of longitudinal and shear velocities in directions perpendicular to the cylinder axis $x_3$. While $F(1,4)$-ZGV frequency slightly depends on $c_{11}$ and more strongly on $c_{44}$ and $c_{66}$ which is proportional to the square of the shear velocity in the direction perpendicular to the cylinder axis. When the values of $c_{11}, c_{13}$, and $c_{33}$ increase or when $c_{44}, c_{66}$ decrease, the F(1,4)-ZGV frequency disappears, i.e., the slope of the spectral line at the cutoff frequency becomes positive. It should be noted that, F(2,1)-ZGV frequency is almost independent of the first four elastic constants while it significantly depends on $c_{66}$.

### IV. RESULTS AND DISCUSSION

In this section, we identify all the resonance frequencies and accurately determine the five elastic constants. The experimental dispersion curves were fitted with those obtained theoretically with the TI model. Then, we compared isotropic and TI models to highlight the anisotropy of the stainless steel cylinder.

#### A. Dispersion curves measurements

Experimental dispersion curves were measured with the laser ultrasound setup displayed in Fig. 1. The out-of-plane displacement was recorded with the interferometer at a single point in the middle of the cylinder, while the line source was moved along the cylinder axis on 40 mm by 0.1 mm steps. For each source position, the normal displacement was recorded during 180 µs at a 50 MHz sampling frequency. To increase the signal to noise ratio, 1024 signals were averaged. First, apodization (Hanning) windows were applied in both dimensions (time and distance) to avoid secondary lobes. Then, a two-dimensional-Fourier transform was applied to the obtained B-scans. Since, cylindrical waveguides support backward-propagation with opposite group and phase velocities, the spatial Fourier transform was extended to negative wave numbers [Fig. 5(b)].

The counter propagative modes are observed in the cylinder both for longitudinal and flexural modes and occur in the vicinity of $k = 0$. For example, at the L(0,2)-ZGV frequency (4.34 MHz) the L(0,2) and L(0,3)b modes having opposite wave vectors interfere.
Figure 4. Influence of the elastic constants on the dispersion curves of a transversely isotropic cylinder. From top to bottom: for longitudinal modes and the first two flexural mode families. Vertical arrows depict the ZGV frequencies and tilted arrows show increasing $c_{ij}$.

The power spectrum was computed at a frequency of 4.40 MHz, slightly higher than the L(0,2)-ZGV resonance frequency, for which the modes are propagative. Figure 5(a), shows that this spectrum is composed of two main peaks. The peak at a negative value of $k$, similar to the larger one in the positive $k$ domain demonstrates the backward propagation in cylinders. Afterwards, the dispersion curves (backward region) for negative wave number $\omega(-k)$ were folded and added to positive ones [Fig. 5(c)]. We can clearly identify five ZGV frequencies. One at 4.34 MHz corresponding to the L(0,2)-ZGV resonance and four others at 2.77, 4.28, 5.60, and 6.60 MHz corresponding to F(2,1), F(3,1), F(4,1), and F(1,4) flexural-ZGV resonances, respectively. The wavelengths at these ZGV frequencies extend from 2.3 to 3.2 mm ($\lambda/2a \sim 3 - 4$) except for F(1,4)-ZGV frequency which has a 14.3 mm wavelength ($\lambda/2a \sim 18.6$).

The theoretical dispersion relation $\omega(k)$ [Eq. (5)] was calculated by solving the secular equation with the zero-finding algorithm. Theoretical dispersion curves were fitted with the TI model. Bulk modes whose bulk velocities are proportional to stiffness constants $c_{33}$ and $c_{44}$ were eliminated by dividing the determinant by $(\rho\omega^2 - c_{33}k^2)(\rho\omega^2 - c_{44}k^2)$. We calculated longitudinal modes and the first seven families of flexural modes. Starting from the two pairs of bulk wave velocities previously determined with the isotropic model, theoretical dispersion curves were fitted heuristically (i.e., without any minimization algorithm) by adjusting the five elastic constants. Finally, we observe [Fig. 5(c)] good agreement between experimental dispersion curves and those predicted by the TI model. The parameters used for the TI model are listed in Table I. The dashed and dotted lines correspond to the longitudinal and first flexural modes respectively, the solid and long-dashed lines in-
Table I. Elastic constants $c_{ij}$ (or sound velocities) used in the TI model. $a$ and $\rho$ were measured.

dicated the flexural modes with $n \geq 2$. Although most modes are well fitted by the theory, a few experimental branches are not explained. This may be due to a small remaining error on the estimated constants or to a slight discrepancy with transverse anisotropy.

B. Elastic parameters

We now explain the physical meaning of the five sound velocities implicitly involved in the TI model. Stiffness constants $c_{11}$ and $c_{33}$ determine the longitudinal (L) ul-
trasonic velocities in perpendicular ($V_{L1}$) and parallel ($V_{L3}$) directions with respect to the cylinder axis $x_3$

$$c_{11} = \rho V_{L1}^2, \quad c_{33} = \rho V_{L3}^2.$$  \hfill (7)

Stiffness constants $c_{44}$ and $c_{66} = (c_{11} - c_{12})/2$ determine the shear (S) velocities in directions perpendicular to the cylinder axis with polarizations either perpendicular ($V_{S1}$) or parallel ($V_{S3}$) to $x_3$-axis

$$c_{44} = \rho V_{S1}^2, \quad c_{66} = \rho V_{S3}^2.$$  \hfill (8)

The remaining stiffness constant $c_{13}$ should be adjusted manually. Hence, two Young’s modulus can be defined: $E_{/ /} = E_{33}$ for a stress parallel to the cylinder axis and $E_{\perp} = E_{11} = E_{22}$ for a stress perpendicular to the cylinder axis. They are given by

$$E_{/ /} = \frac{c^2}{c_{11} - c_{66}}, \quad E_{\perp} = \frac{4c_{66}c_{12}}{c^2 + c_{33}c_{66}},$$  \hfill (9)

where $c^2 = c_{33}(c_{11} - c_{66}) - c_{13}^2$ is the determinant of the sub-matrix of elastic constants $c_{ij}$. This effective stiffness constant $c$ is proportional to the bar velocity of the waves propagating along the cylinder axis: $V_{b} = (E_{/ /}/\rho)^{1/2}$ (see Eq. 44 of Mirsky). Three Poisson’s ratios $\nu_{12}$ and $\nu_{31}$ for longitudinal extension in the basal plane and $\nu_{13}$ along the 6-fold axis

$$\nu_{12} = \frac{c_{12}c_{33} - c_{13}^2}{c^2 + c_{33}c_{66}}, \quad \nu_{31} = \frac{2c_{66}c_{13}}{c^2 + c_{33}c_{66}}, \quad \nu_{13} = \frac{c_{13}}{c_{11} + c_{12}}.$$  

C. Comparison between isotropic and TI model

Theoretical dispersion curves obtained with isotropic (dashed lines) and transversely isotropic (solid lines) models are plotted in Fig. 6. The longitudinal modes are displayed in Fig. 6(a) and the first six flexural mode families [Figures 6(b)-6(g)]. The frequency spectrum recorded at the epicenter is shown in Fig. 6(h). This representation allows to distinguish the different propagation modes and to precisely identify each resonance peak. It obviously appears that the isotropic model is not appropriate to interpret experimental results and clearly confirms the transverse isotropic nature of the cylinder. Five ZGV resonances, $F(2,1)$, $F(3,1)$, $L(0,2)$, $F(4,1)$, $F(1,4)$, and eight circumferential resonances, $F(1,3)$, $L(0,3)$, $F(4,2)$, $F(5,1)$, $F(1,5)$, $F(6,1)$, $F(1,6)$, and $F(2,5)$, can be identified from the dispersion curves calculated with the TI model. Both ZGV and cutoff frequencies are estimated with a relative error less than 0.6%, except for $F_{c}(1,3)$ for which the error is close to 1.1%.

D. Displacements at cutoff frequencies

In order to explain why several circumferential resonances (at $k = 0$) are observed while others are not, we analyzed the displacements generated inside the cylinder.
To this end, we calculated \( u_r, u_\theta, \) and \( u_z \), using Eq. (3). The radial and axial displacements \((u_r)\) and \((u_z)\) were calculated at \( \theta = 0 \) and the azimuthal displacement \((u_\theta)\) at \( \theta_{\text{max}} = \pi/2n \). They are displayed in Fig. 7 at the cutoff frequencies of the modes \( L(0,3), L(0,4), F(1,2), \) and \( F(1,3) \) which respectively correspond to the frequencies 4.834, 8.673, 2.276, and 3.343 MHz. For \( L(0,3) \) and \( F(1,3) \) circumferential resonances, the radial displacement at the cylinder surface \( r = a \) is significant. Conversely, for the modes \( L(0,4) \) and \( F(1,2) \) the radial displacement vanishes for \( r = a \), but have essentially a large displacement along the z-axis. This explains why, at these cutoff frequencies, no resonances are observed.

In summary, elastic guided waves propagating in a stainless steel cylinder of millimetric diameter were investigated by laser ultrasonic techniques. Using a laser line source perpendicular to the cylinder axis, ZGV resonances were observed both for longitudinal and flexural modes.

In the future, it would be useful to build a numerical inversion procedure to improve the accuracy of the material parameter estimation. Furthermore, it will be interesting to investigate the relationship between ZGV modes and elastic constants. This could be done by calculating the second order derivatives of the dispersion curves at cutoff frequencies to determine the existence of backward modes. Finally, it will be interesting to conduct other studies in materials with different types of anisotropy. This technique can be also applied in the sub-gigahertz range with a laser line source of width comparable to the cylinder diameter to study micrometric fibers.

**Appendix**

The scalar functions \( \varphi, \chi, \psi \) satisfy the following wave motion equations:

\[
\begin{align*}
\varphi_{\text{11}} \left( \nabla^2 - \frac{\partial^2}{\partial z^2} \right) \varphi + \left( c_{13} + c_{44} \right) \frac{\partial^2 \psi}{\partial z^2} = \rho \frac{\partial^2 \varphi}{\partial t^2}, \\
\psi_{\text{13}} \left( \nabla^2 - \frac{\partial^2}{\partial z^2} \right) \varphi + \left( c_{13} + c_{44} \right) \frac{\partial^2 \psi}{\partial z^2} = \rho \frac{\partial^2 \psi}{\partial t^2}, \\
\psi_{\text{12}} \left( \nabla^2 - \frac{\partial^2}{\partial z^2} \right) \chi + c_{44} \frac{\partial^2 \chi}{\partial z^2} = \rho \frac{\partial^2 \chi}{\partial t^2}.
\end{align*}
\]

The longitudinal \( L \) (represented by \( \varphi \)) and the vertically polarized quasi-transverse \( SV \) (represented by \( \psi \)) waves are coupled, whereas the pure transverse wave \( SH \) (represented by \( \chi \)) is decoupled from the others. The dispersion equation of torsional, longitudinal, and flexural guided modes in a transversely isotropic cylinder with free boundary conditions results in the vanishing of the determinant of a \( 3 \times 3 \) matrix \( a_{ij} \)

\[
det(a_{ij}) = \begin{cases} 
\begin{align*}
23 & = 0, \\
a_{11}a_{32} - a_{12}a_{31} & = 0, \\
a_{11}(a_{22}a_{33} - a_{23}a_{32}) - a_{12}(a_{21}a_{33} - a_{23}a_{31}) + a_{13}(a_{21}a_{32} - a_{22}a_{31}) & = 0 & \text{for } T(0, m), \\
a_{11}a_{32} - a_{12}a_{31} & = 0, & \text{for } L(0, m), \\
a_{11}(a_{22}a_{33} - a_{23}a_{32}) - a_{12}(a_{21}a_{33} - a_{23}a_{31}) + a_{13}(a_{21}a_{32} - a_{22}a_{31}) & = 0 & \text{for } F(n \geq 1, m),
\end{align*}
\end{cases}
\]

Laurent et al: Resonances in transversely isotropic cylinder
where the matrix elements are
\[ a_{11} = c_{11}(\beta a)^2 J'_n(\beta a) + c_{12} \{(\beta a)J'_n(\beta a) - n^2 J_n(\beta a)\} \]
\[ a_{12} = c_{13}\{ka\}^2 J_n(\beta a), \]
\[ a_{12} = c_{11} q_1(\beta a)^2 J'_n(\beta a) + c_{12} q_2 \{(\beta a)J'_n(\beta a) - n^2 J_n(\beta a)\} \]
\[ a_{13} = 2n c_{66} \{(\beta a)J'_n(\beta a) - J_n(\beta a)\}, \]
\[ a_{21} = -2n \{(\beta a)J'_n(\beta a) - J_n(\beta a)\}, \]
\[ a_{22} = -2n q_2 \{(\beta a)J'_n(\beta a) - J_n(\beta a)\}, \]
\[ a_{23} = -(\beta a)^2 J''_n(\beta a) + (\beta a)J'_n(\beta a) - n^2 J_n(\beta a), \]
\[ a_{31} = (1 + q_1)(\beta a)J'_n(\beta a), \]
\[ a_{32} = (1 + q_2)(\beta a)J'_n(\beta a), \]
\[ a_{33} = n J_n(\beta a), \]
respectively. The first and second derivatives of the Bessel function of the first kind of order \( n \) can be expressed in terms of \( J_{n-1}, J_n, J_{n+1}, \) etc., by using recurrence relations. The coefficients \( E \) and \( F \) used in the Christoffel equation [Eq. (2)] are defined as
\[ E = (c_{13} + c_{44})^2 k^2 + c_{44}(\rho a^2 - c_{44}k^2) + c_{11}(\rho a^2 - c_{33}k^2) \]
\[ = E_1^2 + c_{44} F_1 + c_{11} F_2, \]
\[ F = (\rho a^2 - c_{44}k^2)(\rho a^2 - c_{33}k^2) = F_1 F_2. \]

Finally, the three roots (\( \beta \)) of the Christoffel equation are
\[ \beta_{1,2} = \sqrt{\frac{E + \Delta}{2c_{11}c_{44}}} \text{ and } \beta_3 = \sqrt{\frac{F_1}{c_{66}}}, \]
where \( \Delta = \sqrt{E^2 - 4c_{11}c_{44}F} \). At last, the amplitude ratio \( q_1 \) and \( q_2 \) are given by
\[ q_1 = \frac{F_1 - c_{11}\beta_1^2}{kE_1}, \quad q_2 = \frac{kE_2}{F_1 - c_{11}\beta_2^2}. \]
